Summary: With the aim to mitigate the possible problem of negativity in the estimation of the conditional density function, we introduce a so-called re-weighted Nadaraya-Watson (RNW) estimator. The proposed RNW estimator is constructed by a slight modification of the well-known Nadaraya-Watson smoother. Because the estimator is explicitly defined in terms of the data, its practical implementation is quite simple. With a detailed asymptotic analysis, we demonstrate that the RNW smoother preserves the superior large-sample bias property of the local linear smoother of the conditional density proposed by Fan, Yao and Tong (1996). As a matter of independent statistical interest, the limit distribution of the RNW estimator is also derived.

Key words & phrases: α -mixing, asymptotic properties, negativity, nonparametric, RNW.

1 Introduction

Let $\{(\mathbf{X}_i, Y_i); i \geq 1\}$ be a $\mathbb{R}^d \times \mathbb{R}$ valued strictly stationary process with a common probability density function $f(., .)$ as (\mathbf{X}, Y) . Also assume that \mathbf{X} admits a marginal density $g(.)$. Suppose we are given n observations of (\mathbf{X}, Y) denoted by $(\mathbf{X}_1, Y_1), \dots, (\mathbf{X}_n, Y_n)$. Of interest is estimating the conditional density of Y given $\mathbf{X} = \mathbf{x}$, i.e.

$$f(y|\mathbf{x}) = \frac{f(\mathbf{x}, y)}{g(\mathbf{x})}$$

where $g(.)$ is assumed positive at \mathbf{x} . The conditional density can be a useful statistical tool in several ways. The most obvious need for estimating conditional densities arises when exploring relationships between a response and potential covariates.

A motivating example: Consider the bivariate data analysed by Azzalini and Bowman (1990) on the waiting time between the starts of successive eruptions and the duration of the subsequent eruption for the Old Faithful geyser in Yellowstone National Park, Wyoming. The data were collected from August 1st until August 15th, 1985. There are a total of 299 observations. The times are measured in minutes. In Figure 1 we give a scatter plot of the data. Note that both variables are transformed to have mean zero and variance one. From the plot it is clear that when there has been a relatively short waiting time between eruptions, the duration of the next eruption is relatively long. But, when the waiting time between eruptions is longer than about -0.17 (or 70 minutes in the scale of the untransformed data), the duration of the next eruption is more or less a mixture of short and long durations. This interesting observation can nicely be summarized by the conditional density.

Figure 2 gives the estimated conditional density. Notice that when the waiting time to eruption is more than -0.17, the conditional density of eruption duration conditional on waiting time to eruption is bimodal. On the other hand, for waiting times below -0.17, the conditional density is unimodal. To visually appreciate how the shape of the conditional density evolves across the various values of the waiting time to eruption, the estimated conditional densities in Figure 2 are stacked side-by-side.

In addition to serving as data exploratory or visualization tool, the conditional density can also be useful in time series prediction. Let $\phi_t(Z_t|\Omega_t)$ denote the data-generating

Figure 1: *Duration of eruption plotted against waiting time to eruption.*

Figure 2: *Conditional density estimates of eruption duration conditional on the waiting time to eruption.*

process of a time series $\{Z_t\} \in \mathbb{R}$ where Ω_t contains all relevant variables that explain Z_t . Often the conditioning variables are taken to be past values of Z_t , i.e. $\Omega_t = Z_{t-1}, \dots, Z_{t-m}$ where $m \geq 1$. Suppose data are available on $\{Z_t\}$: Z_1, \dots, Z_N and we like to predict Z_{N+H} ($H \geq 1$). In tackling this problem, by far the most common approach is to model the dependence of future observations on the past by a parametric class of functions, i.e. $\phi_t(\cdot|\cdot)$ is assumed in advance to have a particular form; linear or nonlinear.

An ideal alternative to the parametric based prediction is the nonparametric estima-

tion of the conditional predictive density, i.e. $f_t(z|\Omega_t)$, and use it for prediction purposes. Because the conditional predictive density itself is implied by a data generating process (model) which is unknown, all the information needed to predict the future is summarized in the conditional density without a need for specifying an approximating parametric model. To simplify matters suppose that $m = 1$ and $H = 1$. Define $X_t = Z_t$ and $Y_t = Z_{t+1}$ where $t = 1, \dots, N - 1$. Then the one-step ahead predictive conditional density of Z_{N+1} is simply $f(y|X_N)$. One can use an estimate of $f(y|X_N)$, say $\hat{f}(y|X_N)$, in different ways. For example, point-predictors such as the mean, the median, or the mode can be directly constructed from $\hat{f}(y|X_N)$. More importantly, the whole conditional density can be carefully investigated for unique features that may otherwise been missed by single-point approximations provided by point-predictors. One way of doing this is by reporting predictive intervals (PI's) that better convey the shape of the predictive conditional density (where relevant information is summarized) as much as possible. For instance, Polonik and Yao (2000) proposed a PI called maximum conditional density region (MCDR) that is defined through the conditional predictive density. Because MCDR is constructed in such a way that it reflects a possible multimodality and/or asymmetry of the predictive conditional density, it is an efficient way of reporting PI's when compared against other common ways of PI reporting such as those based on quantiles. Hyndman (1996) and De Gooijer and Gannoun (2000) also introduced methods of defining PI's via the predictive conditional density that are capable of adapting to the shape of the underlying conditional density.

Having recognized the role conditional densities could play in data analysis or time series prediction, the purpose of the present paper is to suggest a nonparametric estimator of the conditional density, $f(y|\boldsymbol{x})$. In particular, our suggestion adapts the conditional distribution smoother of Hall, Wolff and Yao (1999). Cai (2001, 2002) also extended the smoother of Hall *et al.* (1999) to contexts other than the distribution function mainly to conditional quantiles.

The plan of the paper is as follows. In Section 2 we introduce the RNW conditional density smoother. In the same section, two existing smoothers are also discussed so as to motivate the proposed smoother. In Section 3 we study the asymptotic behaviour of the suggested smoother. In Section 4, we provide proof of the main result of the paper. Proofs for some auxiliary results are also given. We close in Section 5 with some

concluding remarks.

2 Methods

To help motivate the construction of the proposed conditional density estimator, we first discuss two existing kernel-based smoothers of the conditional density. To simplify the presentation, we shall consider the case of $d = 1$ throughout the paper.

2.1 Nadaraya-Watson (NW) and local linear

Let the kernel $K(\cdot)$ be a symmetric density function on \mathbb{R} . Let h_n denote the bandwidth. As $h_n \rightarrow 0$, it is easy to see from a standard Taylor argument that

$$E\{K_{h_n}(y - Y)|X = x\} \simeq f(y|x)$$

where $K_{h_n}(\cdot) = K(\cdot/h_n)/h_n$. This suggests that the estimation of $f(y|x)$ can be viewed as a nonparametric regression of $K_{h_n}(y - Y_i)$ on $\{X_i\}$. In fact, it is based on this particular idea that the well-known Nadaraya-Watson kernel smoother, here denoted by $\hat{f}_{NW}(y|x)$, was first proposed by Rosenblatt (1969),

$$\hat{f}_{NW}(y|x) = \sum_{i=1}^n K_{h_n}(y - Y_i)w_i^{NW}(x) \quad (1)$$

where

$$w_i^{NW}(x) = \frac{K_{h_n}(x - X_i)}{\sum_{i=1}^n K_{h_n}(x - X_i)}.$$

Now suppose that the second derivative of $f(y|x)$ exists. Also introduce the short-hand notation,

$$f^{(i,j)}(y|x) = \frac{\partial^{i+j} f(y|x)}{\partial x^i \partial y^j}.$$

In a small neighborhood of a point x , we can approximate $f(y|z)$ locally by a linear term

$$\begin{aligned} f(y|z) &\simeq f(y|x) + f^{(1,0)}(y|x)(z - x) \\ &\equiv a + b(z - x). \end{aligned}$$

In this sense, one can also regard the estimation of $f(y|x)$ as a nonparametric weighted regression of $K_{h_n}(y - Y_i)$ against $(1, (X_i - x))$ using weights $K_{h_n}(x - X_i)$. Accordingly, Fan *et al.* (1996) proposed the so-called local linear smoother of $f(y|x)$. The local linear estimator, here denoted by $\hat{f}_{LL}(y|x)$, is defined as $\hat{a}(x)$, where (\hat{a}, \hat{b}) minimize

$$\sum_{i=1}^n \left(K_{h_n}(y - Y_i) - a - b(X_i - x) \right)^2 K_{h_n}(x - X_i).$$

Simple algebra (see Fan and Gijbels, 1996) shows that $\hat{f}_{LL}(y|x)$ can be expressed as

$$\hat{f}_{LL}(y|x) = \sum_{i=1}^n K_{h_n}(y - Y_i) w_i^{LL}(x), \quad (2)$$

where

$$w_i^{LL}(x) = \frac{K_{h_n}(x - X_i) \{T_{n,2} - (X_i - x)T_{n,1}\}}{(T_{n,0}T_{n,2} - T_{n,1}^2)}$$

with $T_{n,j} = \sum_{i=1}^n K_{h_n}(x - X_i)(X_i - x)^j$ ($j = 0, 1, 2$).

From the definition of the two estimators, we can see that while $\hat{f}_{NW}(y|x)$ approximates $f(y|x)$ locally by a constant, say a , $\hat{f}_{LL}(y|x)$ approximates $f(y|x)$ locally by a linear model. To appreciate why the extension of the local constant fitting to the local linear alternative is interesting, we now compare the two estimators via their respective moments. When the process $\{(X_i, Y_i)\}$ is α -mixing (see Section 3 for a definition of α -mixing), Chen, Linton and Robinson (2001) showed the approximate asymptotic bias and variance of $\hat{f}_{NW}(y|x)$ to be

$$Bias(\hat{f}_{NW}(y|x)) = \frac{1}{2}k_1h_n^2 \left[f^{(2,0)}(y|x) + f^{(0,2)}(y|x) + 2\frac{g'(x)}{g(x)}f^{(1,0)}(y|x) \right], \quad (3)$$

and

$$Var(\hat{f}_{NW}(y|x)) = k_2^2(nh_n^2)^{-1} \frac{f(y|x)}{g(x)} \quad (4)$$

where $k_1 = \int u^2 K(u)du$ and $k_2 = \int K^2(u)du$. Similarly, under ρ -mixing, Fan *et al.* (1996) gave approximate asymptotic bias and variance of $\hat{f}_{LL}(y|x)$, i.e.

$$Bias(\hat{f}_{LL}(y|x)) = \frac{1}{2}k_1h_n^2 \left[f^{(2,0)}(y|x) + f^{(0,2)}(y|x) \right], \quad (5)$$

$$Var(\hat{f}_{LL}(y|x)) = k_2^2(nh_n^2)^{-1} \frac{f(y|x)}{g(x)}. \quad (6)$$

Some remarks about the above asymptotic bias and variance expressions are in order. We see that the two variances are identical. Therefore, the difference in the asymptotic mean squared errors (MSEs) between the two estimators depends only on their respective biases. Note that the bias of $\hat{f}_{NW}(y|x)$ has an extra term $\frac{g'(x)}{g(x)}f^{(1,0)}(y|x)$. The bias of $\hat{f}_{NW}(y|x)$ is large if either $|\frac{g'(x)}{g(x)}|$ or $|f^{(1,0)}(y|x)|$ is large, but neither term appears in (5). For example, when the design density is highly clustered, the term $|\frac{g'(x)}{g(x)}|$ becomes large. Of course, when $g(x)$ is uniform the biases of the two estimators are the same. Thus, the fact that $\hat{f}_{LL}(y|x)$ does not depend on the density of X makes it “design adaptive” (see Fan, 1992). Now, let’s consider $|f^{(1,0)}(y|x)|$. For simplicity, suppose that the conditional density of Y depends on x only through a location parameter, say the conditional mean (denoted here by $m(x)$) and hence $f(y|x) = f(y - m(x))$. Then $f^{(1,0)}(y|x) = m^{(1)}(x)f^{(1,0)}(y - m(x)|x)$ where $m^{(1)}(\cdot)$ denotes the first derivative of $m(\cdot)$. In this set-up, when for example, $m(x)$ is linear $m(x) = a + bx$ with large coefficient b , the bias of $\hat{f}_{NW}(y|x)$ gets large. But, when $m(x)$ is flat or has maximum or minimum, or inflection point at x , the biases of the two estimators become the same.

The above theoretical comparisons suggest that the local linear estimator is more attractive than the local constant alternative because of its better bias performance and design adaptation. It is also possible to show that both in the interior and near the boundary of the support of $g(\cdot)$, the asymptotic bias and the variance of $\hat{f}_{LL}(y|x)$ are of the same order of magnitude. On the other hand, $\hat{f}_{NW}(y|x)$ has a bias of order h_n for x in the boundary. So, at least in theory, the local linear smoother does not suffer from boundary effects and hence does not require modifications at the boundaries.

Although the local linear approach is more efficient in the sense already discussed, the smoother $\hat{f}_{LL}(y|x)$ may give conditional density function estimates that are not constrained to be nonnegative. On the other hand, $\hat{f}_{NW}(y|x)$ always gives nonnegative estimates. With these remarks in mind, we pass on to the suggestion of this paper.

2.2 RNW estimator

Now we introduce a simple kernel smoother called RNW which combines the better sides of the LL and NW smoothers. In other words, while sharing the nice sampling properties

of the LL estimator, it is always nonnegative.

From least squares theory, it is easy to see that the local linear weights $w_i^{LL}(x)$ satisfy: $\sum_{i=1}^n (X_i - x)w_i^{LL}(x) = 0$. But for the Nadaraya-Watson weights $w_i^{NW}(x)$, this moment condition is not fulfilled. It is this observation that motivates the introduction of the RNW smoother. Let $\tau_i(x)$ denote probability like weights with properties that $\tau_i(x) \geq 0$, $\sum_{i=1}^n \tau_i(x) = 1$, and

$$\sum_{i=1}^n \tau_i(x)(X_i - x)K_{h_n}(x - X_i) = 0. \quad (7)$$

Note how $\tau_i(x)$ is introduced to force the Nadaraya-Watson weights $w_i^{NW}(x)$ resemble that of $w_i^{LL}(x)$ (see also Hall and Presnell, 1999). Following similar arguments as in Owen (1988), we look for the unique solution of $\tau_i(x)$ by maximizing $\sum_{i=1}^n \log\{\tau_i(x)\}$ subject to the above constraints via Lagrange multipliers, i.e.

$$G = \sum_{i=1}^n \log\{\tau_i(x)\} + \kappa \left(1 - \sum_{i=1}^n \tau_i(x)\right) - n\lambda \sum_{i=1}^n \tau_i(x)(X_i - x)K_h(x - X_i).$$

Setting $\partial G / \partial \tau_i(x) = 0$, one obtains $\tau_i(x) = 1 / \{\kappa + n\lambda(X_i - x)K_{h_n}(x - X_i)\}$. But, just summing $\partial G / \partial \tau_i(x)$ and employing (7), we can see that $\kappa = n$. Hence,

$$\tau_i(x) = n^{-1} \{1 + \lambda(X_i - x)K_{h_n}(x - X_i)\}^{-1}. \quad (8)$$

Now we show that $|\lambda| \leq O_p(h_n)$. This is a useful intermediate result in studying the asymptotic theory of the RNW smoother. Let $v_i = (X_i - x)K_{h_n}(x - X_i)$. Then from (7) and (8),

$$n^{-1} \sum_{i=1}^n v_i \{1 + \lambda v_i\}^{-1} = 0.$$

Rewriting this

$$\begin{aligned} 0 &= n^{-1} \sum_{i=1}^n \{\lambda v_i^2 (1 + \lambda v_i)^{-1} - v_i\} \\ &= n^{-1} \left| \sum_{i=1}^n \{\lambda v_i^2 (1 + \lambda v_i)^{-1} - v_i\} \right| \\ &\geq \left| \lambda n^{-1} \sum_{i=1}^n v_i^2 (1 + \lambda v_i)^{-1} \right| - |\bar{v}_1| \end{aligned}$$

where $\bar{v}_1 = n^{-1} \sum_{i=1}^n v_i$. But notice that

$$|1 + \lambda v_i|^{-1} \geq (1 + |\lambda| \max(|v_i|))^{-1}.$$

Thus continuing,

$$0 \geq |\lambda|(1 + |\lambda|C_2)^{-1}\bar{v}_2 - |\bar{v}_1|,$$

where $\bar{v}_2 = n^{-1} \sum_{i=1}^n v_i^2$ and C_2 denotes the upper bound to v_i . Hence,

$$|\lambda|(1 + C_2|\lambda|)^{-1}\bar{v}_2 \leq |\bar{v}_1|.$$

This implies,

$$|\lambda| \leq \frac{|\bar{v}_1|}{\bar{v}_2 - C_2|\bar{v}_1|}.$$

Now, by standard Taylor expansion, it follows easily that

$$\bar{v}_1 = O_p(h_n^2), \quad \text{and} \quad \bar{v}_2 = O_p(h_n).$$

Therefore, $|\lambda| \leq O_p(h_n)$.

Definition and computation

The RNW smoother looks very much like that of NW smoother. The only difference is that it involves re-weighting the NW weights by $\tau_i(x)$. The role of $\tau_i(x)$ is to adjust the NW weights such that resulting conditional density estimates resemble that from the LL smoother. We define the RNW conditional density estimator as follows

$$\hat{f}_{RNW}(y|x) = \sum_{i=1}^n K_{h_n}(y - Y_i) w_i^{RNW}(x) \tag{9}$$

where

$$w_i^{RNW}(x) = \frac{\tau_i(x) K_{h_n}(x - X_i)}{\sum_{i=1}^n \tau_i(x) K_{h_n}(x - X_i)}.$$

From computational perspective the RNW smoother is easy to implement. To see that, let's substitute (8) into (7). Upon doing this, we obtain

$$0 = \sum_{i=1}^n \frac{(X_i - x) K_{h_n}(x - X_i)}{1 + \lambda(X_i - x) K_{h_n}(x - X_i)} \equiv g(\lambda).$$

Now notice that $-g(\cdot)$ is just the gradient with respect to λ of

$$L(\lambda) = - \sum_{i=1}^n \log\{1 + \lambda(X_i - x)K_{h_n}(x - X_i)\}.$$

So a zero of $g(\cdot)$ is a stationary point of $L(\cdot)$. The implication is that, in practice, one can compute λ as the unique minimizer of $L(\cdot)$. Our experience suggests that a line search algorithm is a suitable choice to compute λ . The conditional densities displayed in Section 1 are computed via the RNW smoother.

3 Asymptotic behaviour

In this section, our aim is to study the asymptotic properties of the *RNW* conditional density estimator $\hat{f}_{RNW}(y|x)$ under a reasonably weak mixing condition. In particular, we consider the so-called strong mixing (α -mixing). This mixing condition ensures an asymptotically vanishing memory of the strictly stationary process. The α -mixing condition (Rosenblatt, 1956) is satisfied if there exists a sequence of nonnegative numbers called mixing coefficients ($\alpha(k)$) such that $\lim_{k \rightarrow \infty} \alpha(k) = 0$ and for any A in $\mathcal{F}_1^n = \sigma\{(X_1, Y_1), \dots, (X_n, Y_n)\}$ and any set B in $\mathcal{F}_{n+k}^\infty = \sigma\{(X_{n+k}, Y_{n+k}), \dots\}$, we have $|P(A \cap B) - P(A)P(B)| \leq \alpha(k)$.

The α -mixing condition is weaker than many other mixing modes and dependence conditions, for example, m -dependent, ϕ -mixing, absolute regular, and ρ -mixing. Further, it is known that α -mixing is fulfilled for many stochastic processes, including many time series models. For example, under mild assumptions, linear AR and bilinear time series models are strongly mixing, with mixing coefficients decaying exponentially. For more details on mixing conditions, we refer the interested reader to, for example, Roussas and Ioannides (1987).

Before we state the results of this paper, we first provide a list of regularity conditions that are useful in asymptotic theory of *RNW* smoother. For brevity, theoretical results will be given for x in the interior of the support of X .

A.1 The kernel function $K(\cdot)$ is a probability density function defined on the real line such that:

(i) K is bounded and symmetric.

(ii) $|u|K(u) \rightarrow 0$ as $|u| \rightarrow 0$.

(iii) $\int u^2 K(u) du < \infty$.

A.2 (i) The marginal density $g(x)$ is continuous and is bounded from below by a positive constant.

(ii) The function $f(y|x)$ has bounded continuous second order derivative with respect to x at (x, y) .

A.3 $E(|K_{h_n}(y - Y_1)|^\ell | X_1 = u) \leq C < \infty$ for some $\ell > 2$, in a neighborhood of x .

A.4 The joint conditional density $f_{(Y_1, Y_j)|(X_1, X_j)}$ of (Y_1, Y_j) given (X_1, X_j) satisfies, for all $j > 1$ and all values of arguments involved,

$$f_{(Y_1, Y_j)|(X_1, X_j)}(y_1, y_j | u, v) \leq C < \infty.$$

A.5 As $n \rightarrow \infty$, $h_n \rightarrow 0$ and $nh_n^2 \rightarrow \infty$.

A.6 (i) There exists a sequence of positive integers $\{d_n\}$ such that $d_n \rightarrow \infty$ and $d_n h_n^2 \rightarrow 0$.

(ii) For some constant δ , $0 < \delta < 1$, and $a > \delta$, $\sum_{j=1}^{\infty} j^a \alpha^\delta(j) < \infty$.

A.7 Assume that there exists a sequence of positive integers, q_n such that $q_n \rightarrow \infty$, $q_n = o((nh_n^2)^{1/2})$, and $(n/h_n^2)^{1/2} \alpha(q_n) \rightarrow 0$ as $n \rightarrow \infty$.

Remark 1: We provide a sufficient condition for the mixing coefficient $\alpha(n)$ to satisfy Conditions A.6(ii) and A.7. Suppose that $h_n = An^{-0.5\rho}$ ($0 < \rho < 1, A > 0$), $q_n = (nh_n^2/\log n)^{1/2}$ and $\alpha(n) = O(n^{-d})$ for some $d > 0$. Note that such choice of $\alpha(n)$ encompasses a large class of strongly mixing random variables with mixing coefficients decaying moderately fast. Then Condition A.6(ii) is satisfied for $d > (\delta + 1)/\delta$ and Condition A.7 is satisfied if $d > (1 + \rho)/(1 - \rho)$. Hence, both conditions are satisfied if

$$\alpha(n) = O(n^{-d}), \quad \text{and} \quad d > \max \left\{ \frac{1 + \rho}{1 - \rho}, \frac{\delta + 1}{\delta} \right\}.$$

Theorem: Assume that Conditions A.1-A.7 are satisfied and suppose that $(nh_n^6)^{1/2}$ tends to a constant c . Then, as $n \rightarrow \infty$, we have

(i)

$$\hat{f}_{RNW}(y|x) - f(y|x) = Bias(\hat{f}_{RNW}(y|x)) + O_p((nh_n^2)^{-1/2}),$$

(ii)

$$(nh_n^2)^{1/2} \left[\hat{f}_{RNW}(y|x) - f(y|x) - Bias(\hat{f}_{RNW}(y|x)) \right] \xrightarrow{D} \mathcal{N}\left(0, \frac{k_2^2 f(y|x)}{g(x)}\right)$$

where

$$Bias(\hat{f}_{RNW}(y|x)) = \frac{1}{2} k_1 h_n^2 [f^{(2,0)}(y|x) + f^{(0,2)}(y|x)]. \quad (10)$$

Remark 2: From Theorem (i), it may be seen that to the first order, the RNW smoother enjoys the same convergence rates as the LL smoother of Fan *et al.* (1996). However, they employed the ρ -mixing condition which is stronger than the α -mixing.

Remark 3: From Theorem (ii), the asymptotic variance is given as

$$Var(\hat{f}_{RNW}(y|x)) = k_2^2 (nh_n^2)^{-1} \frac{f(y|x)}{g(x)}.$$

Note that to the first order, $\hat{f}_{RNW}(y|x)$ matches both the bias and the variance of the local linear smoother $\hat{f}_{LL}(y|x)$ (see (5)). Thus, the RNW smoother shares the better bias behaviour of the LL smoother.

Remark 4: If one chooses the optimal bandwidth, say h_n^* , such that it minimizes the asymptotic MSE of $\hat{f}_{RNW}(y|x)$, it is easy to see that

$$h_n^* = Bn^{-1/6}$$

where B is a function of some unknowns such as $f(y|x)$. In practice, B may be replaced by consistent estimates in order to construct a feasible, approximately optimal bandwidth.

Unlike the $n^{-1/5}$ rate familiar from the univariate density estimation, notice that $h_n^* \sim n^{-1/6}$ as one needs to smooth in both x and y directions.

Remark 5: In defining all the kernel smoothers of the conditional density including the RNW smoother, we have used the same bandwidth h_n in both x and y directions. But in practice there may arise a need to have different levels of smoothing for each direction. For example, in the eruption-waiting time illustration of Section 1, it is not advisable to have the same bandwidth for both variables because they have different levels of variability. In fact that was the reason for standardizing the variables before using a single bandwidth for both.

Remark 6: As seen in Remark 4, the optimal bandwidth choice under the MSE criterion gives h_n satisfying $nh_n^6 \rightarrow c^2 \neq 0$. If $nh_n^6 \rightarrow 0$, the bias will be negligible, the asymptotic MSE will be dominated by the variance and hence we are not in the optimal case. So the imposed condition that $(nh_n^6)^{1/2} \rightarrow c \neq 0$ allows us to give an asymptotic normality theorem under optimal conditions of convergence.

4 Proofs

Throughout this section we re-denote $\hat{f}_{RNW}(y|x)$ by $\hat{f}(y|x)$. In the course of the proof of the theorem, we also derive some auxiliary results which are necessary to establish the theorem. All along this chapter C will denote a generic constant.

4.1 Proof of the theorem

The first step in the proof is to get an arbitrary good approximation to the value of λ . Recall that $|\lambda| \leq O_p(h_n)$. After replacing $\tau_i(x)$ by (8), we Taylor expand (7) about $\lambda = 0$. This gives

$$\lambda = \frac{h_n k_1 g'(x)}{k_3 g(x)} + o_p(h_n) \quad (11)$$

where $k_3 = \int u^2 K^2(u) du$. Now substituting (11) into (8),

$$\tau_i(x) = n^{-1} b_i(x) (1 + o_p(1)) \quad (12)$$

where

$$b_i(x) = \left(1 + \frac{h_n k_1 g'(x)}{k_3 g(x)} (X_i - x) K_{h_n}(x - X_i)\right)^{-1}.$$

Let $m(x, y) = E\{K_{h_n}(y - Y)|X = x\}$. Also define $\varepsilon_i = K_{h_n}(x - X_i) - m(X_i, y)$. Using (9) and (12),

$$\begin{aligned} \hat{f}(y|x) - f(y|x) &= \frac{n^{-1} \sum_{i=1}^n [\varepsilon_i + m(X_i, y) - f(y|x)] b_i(x) K_{h_n}(x - X_i)}{n^{-1} \sum_{i=1}^n b_i(x) K_{h_n}(x - X_i)} \{1 + o_p(1)\} \\ &\equiv \{(nh_n^2)^{-1/2} J_1 + J_2\} J_3^{-1} \{1 + o_p(1)\} \end{aligned} \quad (13)$$

where

$$\begin{aligned} J_1 &= h_n n^{-1/2} \sum_{i=1}^n b_i(x) \varepsilon_i K_{h_n}(x - X_i), \\ J_2 &= n^{-1} \sum_{i=1}^n [m(X_i, y) - f(y|x)] b_i(x) K_{h_n}(x - X_i), \quad \text{and} \\ J_3 &= n^{-1} \sum_{i=1}^n b_i(x) K_{h_n}(x - X_i). \end{aligned}$$

It is easy to see that $m(x, y) = f(y|x) + \frac{1}{2} k_1 h_n^2 f^{(0,2)}(y|x) + o_p(h_n^2)$ and its second derivative with respect to x , $m^{(2)}(x, y) = f^{(2,0)}(y|x) + \frac{1}{2} k_1 h_n^2 f^{(2,2)}(y|x)$. By Taylor expanding $m(X_i, y)$ about $X_i = x$ to the second order and employing (7), J_2 becomes

$$\begin{aligned} J_2 &= \frac{1}{2} h_n^2 k_1 f^{(0,2)} n^{-1} \sum_{i=1}^n b_i(x) K_{h_n}(x - X_i) + \\ &\quad \frac{1}{2} m^{(2)}(x, y) n^{-1} \sum_{i=1}^n (X_i - x)^2 b_i(x) K_{h_n}(x - X_i) + o_p(h_n^2). \end{aligned}$$

Using the expression for $m^{(2)}(x, y)$ and further Taylor expansion gives

$$J_2 = \frac{1}{2} k_1 h_n^2 g(x) \left\{ f^{(2,0)}(y|x) + f^{(0,2)}(y|x) \right\} + O_p(h_n^4) + o_p(h_n^2).$$

Similar manipulation applied to J_3 gives $J_3 = g(x) + o_p(1)$. Substituting the evaluated J_2 and J_3 , (13) becomes

$$(nh_n^2)^{1/2} \left[\hat{f}(y|x) - f(y|x) - Bias(\hat{f}(y|x)) + o_p(h_n^2) \right] = g^{-1}(x) J_1 + o_p(1) \quad (14)$$

where $Bias(\hat{f}(y|x))$ is as defined in (10). Note that since the condition $(nh_n^6)^{1/2} \rightarrow c$ implies $(nh_n^2)^{1/2} o_p(h_n^2) = o_p(1)$, 14 becomes

$$(nh_n^2)^{1/2} \left[\hat{f}(y|x) - f(y|x) - Bias(\hat{f}(y|x)) \right] = g^{-1}(x) J_1 + o_p(1). \quad (15)$$

To deal with J_1 , we evaluate $E(J_1)$ and $Var(J_1)$. Set $\Delta_i = h_n \varepsilon_i b_i(x) K_{h_n}(x - X_i)$, then

$$J_1 = n^{-1/2} \sum_{i=1}^n \Delta_i.$$

Note that $E(\Delta_i) = 0$. Thus $E(J_1) = 0$. Exploiting stationarity

$$\begin{aligned} Var(J_1) &= E(\Delta_i^2) + 2n^{-1} \sum_{1 \leq i < j \leq n} E(\Delta_i \Delta_j) \\ &= E(\Delta_1^2) + 2 \sum_{j=2}^n \left(1 - \frac{j-1}{n}\right) E(\Delta_1 \Delta_j). \end{aligned} \quad (16)$$

From routine calculations, it follows that

$$E(\Delta_1^2) = g(x) k_2^2 f(y|x) + o_p(1).$$

It remains to evaluate the second term of (16). For notational convenience, we shall denote this term by B . We follow the technique by Masry (Masry, 1986). Namely, define the sets S_1 , and S_2 by

$$\begin{aligned} S_1 &= \{(1, j) : j \in \{1, \dots, n\}, \quad 1 \leq j-1 \leq d_n\} \\ S_2 &= \{(1, j) : j \in \{1, \dots, n\}, \quad d_n + 1 \leq j-1 \leq n-1\} \end{aligned}$$

where $\{d_n\}$ is as defined in Condition A.5(i).

From the above splitting, notice that

$$B = 2 \sum_{j \in S_1} \left(1 - \frac{j-1}{n}\right) E(\Delta_1 \Delta_j) + 2 \sum_{j \in S_2} \left(1 - \frac{j-1}{n}\right) E(\Delta_1 \Delta_j). \quad (17)$$

Consider the first term on the right-hand side of B (or (17)), i.e.

$$\begin{aligned} 2 \sum_{j \in S_1} \left(1 - \frac{j-1}{n}\right) E(\Delta_1 \Delta_j) &\leq \sum_{j=1}^{d_n} |E(\Delta_1 \Delta_j)| \\ &\leq \sum_{j=1}^{d_n} C h_n^2, \quad \text{by Lemma 1(ii)} \\ &= C d_n h_n^2 = o(1). \end{aligned} \quad (18)$$

The last step follows from Condition A.5(i).

For the second term on the right-hand side of (17), note that

$$2 \sum_{j \in S_2} \left(1 - \frac{j-1}{n}\right) E(\Delta_1 \Delta_j) \leq \sum_{j \in S_2} |E(\Delta_1 \Delta_j)|.$$

Applying Davydov's (1970) inequality, we have that

$$\sum_{j \in S_2} |E(\Delta_1 \Delta_j)| \leq \sum_{j \in S_2} 8\alpha^\delta (j-1) E^{1/s}(|\Delta_1|^s) E^{1/t}(|\Delta_1|^t)$$

where $1/s + 1/t = 1 - \delta$ and δ is as defined in Condition A.5(ii). Now setting $s = t = \ell$,

$$\begin{aligned} \sum_{j \in S_2} |E(\Delta_1 \Delta_j)| &\leq \sum_{j \in S_2} 8\alpha^\delta (j-1) E^{(1-\delta)}(|\Delta_1|^\ell) \\ &\leq 8 \sum_{j \in S_2} \alpha^\delta (j-1) (Ch_n)^{1-\delta}, \quad \text{by Lemma 1(i)} \\ &\leq Ch_n^{1-\delta} \sum_{j=d_n+1}^{n-1} (n-j) \alpha^\delta(j) \\ &\leq Ch_n^{1-\delta} \sum_{j=d_n}^{\infty} \alpha^\delta(j) \\ &\leq Ch_n^{1-\delta} d_n^{-a} \sum_{j=d_n}^{\infty} j^a \alpha^\delta(j). \end{aligned}$$

Lets choose d_n such that $h_n^\delta d_n^a = O(h_n)$. Then, using Condition A.5(ii), we have $\sum_{j \in S_2} |E(\Delta_1 \Delta_j)| = o(1)$. Observe that under the above choice of d_n , the condition $d_n h_n^2 \rightarrow 0$ is satisfied. Substituting the above evaluated terms into (16), we can see that

$$\text{Var}(J_1) \rightarrow g(x) k_2^2 f(y|x). \quad (19)$$

Finally, recalling (15),

$$\hat{f}(y|x) - f(y|x) = \text{Bias}(\hat{f}(y|x)) + O_p((nh_n^2)^{-1/2}).$$

This completes the proof of the first part of the theorem.

Denoting $\text{Var}(J_1)$ by $\sigma^2(x, y)$, we now move to the second part of the theorem, i.e. to show that the left-hand side of (15) is asymptotically normally distributed. To achieve this, it is sufficient to establish that J_1 is $\mathcal{N}(0, \sigma^2(x, y))$ distributed.

For the proof we make use of Doob's technique (see Doob, 1953, pp. 228-232) according to which the sum $\sum_{i=1}^n \Delta_i$ is split into large and small blocks. Specifically, we partition $\{1, \dots, n\}$ into $2r_n + 1$ subsets with large block of size p_n and small block of size q_n . Set

$$r_n = \left\lfloor \frac{n}{p_n + q_n} \right\rfloor$$

where $[\cdot]$ denotes the integer part. Thus, we can write J_1 as,

$$J_1 = n^{-1/2} \sum_{i=1}^n \Delta_i = n^{-1/2} \{S_{1,n} + S_{2,n} + S_{3,n}\}$$

where

$$S_{1,n} = \sum_{j=1}^{r_n} \eta_j, \quad S_{2,n} = \sum_{j=1}^{r_n} \epsilon_j, \quad S_{3,n} = \omega_{r_n}$$

with

$$\begin{aligned} \eta_j &= \sum_{i=k_j}^{k_j+p_n-1} \Delta_i, \quad \text{where } k_j = (j-1)(p_n + q_n) + 1, \\ \epsilon_j &= \sum_{i=l_j}^{l_j+q_n-1} \Delta_i, \quad \text{where } l_j = (j-1)(p_n + q_n) + p_n + 1, \\ \omega_{r_n} &= \sum_{i=r_n(p_n+q_n)+1}^n \Delta_i. \end{aligned}$$

Before continuing with the proof, we first show some consequences of Condition A.6. This condition implies that there is a sequence of positive constants $\beta_n \rightarrow 0$ such that

$$\beta_n q_n = o((nh^2)^{1/2}) \quad \text{and} \quad \beta_n (n/h^2)^{1/2} \alpha(q_n) \rightarrow 0. \quad (20)$$

Now define p_n by $p_n = \lceil (nh^2)^{1/2} / \beta_n \rceil$. Then it follows easily from (20) that as $n \rightarrow \infty$,

$$q_n/p_n \rightarrow 0, \quad p_n/n \rightarrow 0, \quad p_n(nh^2)^{-1/2} \rightarrow 0, \quad \text{and} \quad (n/p_n)\alpha(q_n) \rightarrow 0. \quad (21)$$

Now we exploit Lemma 2. This Lemma tells us that $S_{2,n}$ and $S_{3,n}$ are asymptotically negligible. Then showing the asymptotic normality of J_1 reduces to proving that $n^{-1/2}S_{1,n}$ converges to $\mathcal{N}(0, \sigma^2(x, y))$. The main idea of the proof is to approximate $n^{-1/2}S_{1,n}$ by a sum of independent random variables (r.v.'s). For each n , let $z_{n,1}, \dots, z_{n,r}$ denote independent r.v.'s with the distribution that of

$$n^{-1/2}\eta_1 = n^{-1/2} \sum_{j=1}^{p_n} \Delta_j.$$

Then, the characteristics function (cf.) of $\sum_{m=1}^r z_{n,m}$ is $\Phi_{p_n}^{r_n}(tn^{-1/2})$, where $\Phi_{p_n}(tn^{-1/2})$ is the cf. of $n^{-1/2}\eta_1$. Notice that η_a is $\mathcal{F}_{i_a}^{j_a}$ -measurable with $i_a = (a-1)(p_n + q_n) + 1$ and $j_a = i_a + p_n - 1$. Let $V_j = \exp(it\eta_j/\sqrt{n})$, then using Lemma 4,

$$\begin{aligned} \left| E[\exp(itn^{-1/2}S_{1,n})] - \Phi_p^r(tn^{-1/2}) \right| &= \left| E[\exp(itn^{-1/2}S_{1,n})] - \prod_{j=1}^r E[\exp(itn^{-1/2}\eta_j)] \right| \\ &\leq 16r\alpha(q_n + 1) \rightarrow 0. \end{aligned}$$

The last step follows from (21), i.e. $r_n \alpha(q_n) \leq (n/p_n) \alpha(q_n) \rightarrow 0$. Therefore, it suffices to establish that $\Phi_{p_n}^{r_n}(tn^{-1/2})$ converges to the cf. of the $\mathcal{N}(0, \sigma^2(x, y))$. Equivalently, it would suffice to show that $\sum_{m=1}^{r_n} Z_{n,m}$ is asymptotically $\mathcal{N}(0, 1)$, where

$$Z_{n,m} = z_{n,m}/s_n, \quad s_n^2 = \sum_{m=1}^{r_n} E(z_{n,m}^2) = \frac{r_n}{n} E(\eta_1^2).$$

Now $\sum_{m=1}^{r_n} Z_{n,m}$ will converge to $\mathcal{N}(0, 1)$ provided that, for every $\varepsilon > 0$,

$$g_n(\varepsilon) = \sum_{m=1}^{r_n} \int_{|x| > \varepsilon} x^2 dF_{n,m}(x) \rightarrow 0, \quad \text{as } n \rightarrow \infty,$$

where $F_{n,m}(\cdot)$ is the distribution function of $Z_{n,m}$. This is the well-known Lindeberg condition. But, since $F_{n,m}(\cdot)$ is the same for $m = 1, \dots, r_n$,

$$\begin{aligned} g_n(\varepsilon) &= r_n E\left(Z_{n,1}^2 \mathbf{1}_{\{|Z_{n,1}| \geq \varepsilon\}}\right), \\ &= \frac{r_n}{n s_n^2} E\left(\eta_1^2 \mathbf{1}_{\{|\eta_1| \geq \sqrt{n} s_n \varepsilon\}}\right), \\ &\leq \frac{r_n p_n^2 C^2}{n s_n^2} P(|\eta_1| \geq \varepsilon \sqrt{n} s_n) \quad \text{since } |\eta_1| \leq p_n C, \\ &\leq \frac{r_n p_n^2 C^2}{n s_n^2} \frac{E(\eta_1^2)}{\varepsilon^2 n s_n^2} \quad \text{by Markov inequality,} \\ &\leq \frac{C^2 p_n^2}{\varepsilon^2 n s_n^2}. \end{aligned}$$

By Lemma 3, $E(\eta_1^2) \rightarrow p_n \sigma^2(x, y)$. Further, from (21), it is easy to see that $p_n r_n / n \rightarrow 1$ (see the proof of Lemma 2). Thus, $s_n^2 \rightarrow \sigma^2(x, y) \neq 0$. Again from (21), $p_n^2 / n \rightarrow 0$. Therefore, $g_n(\varepsilon) \rightarrow 0$. Hence $\sum_{m=1}^{r_n} Z_{n,m}$ will converge to $\mathcal{N}(0, 1)$, or equivalently $\sum_{m=1}^{r_n} z_{n,m}$ will converge to $\mathcal{N}(0, \sigma^2(x, y))$. This completes the proof of the theorem.

4.2 Auxiliary results

Lemma 1: *Under the conditions of the Theorem,*

$$(i) \quad E(|\Delta_1|^\ell) \leq C h_n;$$

$$(ii) \quad |E(\Delta_1 \Delta_j)| \leq C h_n^2.$$

Proof:

(i) Recall that $\Delta_1 = h_n \varepsilon_1 b_1(x) K_{h_n}(x - X_1)$. Note that

$$E(|\Delta_1|^\ell) = h^\ell \int_{\mathbb{R}} \int_{\mathbb{R}} |(K_{h_n}(y - Y_1) - m(X_1, y)) b_1(x) K_{h_n}(x - X_1)|^\ell f(X_1, Y_1) dX_1 dY_1.$$

Now conditioning on $X_1 = u$, noting that $m(X_1, y)$ is bounded and using Conditions A.2(i) and A.3, we can see that

$$\begin{aligned} E(|\Delta_1|^\ell) &\leq Ch_n^\ell \int_{\mathbb{R}} |b_1(x) K_{h_n}(x - u)|^\ell du \\ &\leq Ch_n. \end{aligned}$$

The last step follows from applying Condition A.1(ii).

(ii) Clearly

$$\begin{aligned} E(\Delta_1 \Delta_j) &= h_n^2 \int_{\mathbb{R}} \int_{\mathbb{R}} \int_{\mathbb{R}} \int_{\mathbb{R}} \varepsilon_1 b_1(x) K_{h_n}(x - X_1) \varepsilon_j \times \\ &\quad b_j(x) K_{h_n}(x - X_j) f_{(X_1, Y_1, X_j, Y_j)}(x_1, y_1, x_j, y_j) dx_1 dy_1 dx_j dy_j. \end{aligned}$$

Conditioning on $(X_1, X_j) = (u, v)$ and using Condition A.4,

$$\begin{aligned} |E(\Delta_1 \Delta_j)| &\leq Ch_n^2 \int_{\mathbb{R}} \int_{\mathbb{R}} |\varepsilon_1 b_1(x) K_{h_n}(x - u) \varepsilon_j b_j(x) K_{h_n}(x - v)| f_{(X_1, X_j)}(u, v) dudv \\ &\leq Ch_n^2 \left(\int_{\mathbb{R}} |b_1(x) K_{h_n}(x - u)| du \right)^2 \\ &\leq Ch_n^2. \end{aligned}$$

Lemma 2: Under conditions of the Theorem, $n^{-1}E(S_{2,n}^2) = o(1)$ and $n^{-1}E(S_{3,n}^2) = o(1)$.

Proof: Here we only prove $n^{-1}E(S_{n,2}^2) = o(1)$. The proof of $n^{-1}E(S_{n,3}^2) = o(1)$ can be done along the same lines. Observe that

$$E(S_{n,2}^2) = \sum_{j=1}^{r_n} E(\epsilon_j^2) + 2 \sum_{1 \leq u < j \leq r_n} E(\epsilon_u \epsilon_j). \quad (22)$$

Consider the first term on the right-hand side of (22). In the rest of the proof, the stationarity property will be repeatedly used. We can see that

$$\sum_{j=1}^{r_n} E(\epsilon_j^2) = \sum_{j=1}^{r_n} \left[\sum_{i=\ell_j}^{\ell_j + q_n - 1} E(\Delta_i^2) + 2 \sum_{\ell_j \leq m < i \leq \ell_j + q_n - 1} E(\Delta_m \Delta_i) \right]$$

$$\begin{aligned}
&= \sum_{j=1}^{r_n} \left[\sum_{i=\ell_j}^{\ell_j+q_n-1} E(\Delta_i^2) + 2q_n \sum_{i=2}^{q_n} \left(1 - \frac{i}{q_n}\right) E(\Delta_1 \Delta_i) \right] \\
&\leq \sum_{j=1}^{r_n} \left[q_n E(\Delta_1^2) + 2q_n \sum_{i=2}^{q_n} \left(1 - \frac{i}{q_n}\right) |E(\Delta_1 \Delta_i)| \right] \\
&\leq \sum_{j=1}^{r_n} \left[q_n E(\Delta_1^2) + 2q_n \sum_{i=2}^{q_n} |E(\Delta_1 \Delta_i)| \right] \\
&\leq r_n q_n \left(E(\Delta_1^2) + o(1) \right). \tag{23}
\end{aligned}$$

The last step follows from applying similar arguments used in deriving the variance of J_1 . Now we deal with the second term of (22). When $u \neq k$,

$$\sum_{1 \leq u < j \leq r_n} E(\epsilon_u \epsilon_j) = \sum_{u=1}^{r_n} \sum_{k=1}^{r_n} \sum_{i=1}^{q_n} \sum_{j=1}^{q_n} E(\Delta_{u(p_n+q_n)+p_n+i} \Delta_{k(p_n+q_n)+p_n+j}).$$

But since, $|u(p_n + q_n) + p_n + i - (k(p_n + q_n) + p_n + j)| \geq p_n$,

$$\begin{aligned}
2 \sum_{1 \leq u < j \leq r_n} E(\epsilon_u \epsilon_j) &\leq 2 \sum_{i=1}^{n-p_n} \sum_{j=i+p_n}^n |E(\Delta_i \Delta_j)| \\
&\leq 2n \sum_{j=1+p_n}^n |E(\Delta_1 \Delta_j)| \\
&= o(n). \tag{24}
\end{aligned}$$

Note that $\sum_{j=1+p_n}^n |E(\Delta_1 \Delta_j)| = o(1)$. Now combining (23) and (24),

$$n^{-1} E(S_{n,2}^2) \leq n^{-1} \left(r_n q_n E(\Delta_1^2) + o(1) + o(n) \right).$$

But from (20) $r_n q_n / n \leq q_n / (p_n + q_n)$. Further, from (21), $q_n / p_n \rightarrow 0$. Therefore, $r_n q_n / n \rightarrow 0$. Thus the proof of the lemma is complete.

Lemma 3: *Under conditions of the Theorem,*

$$E(\eta_1^2) \rightarrow p_n \sigma^2(x, y).$$

Proof: Recall that $\eta_1 = \sum_{j=1}^{p_n} \Delta_j$. Then

$$E(\eta_1^2) = \sum_{j=1}^{p_n} E(\Delta_j^2) + 2 \sum_{1 \leq j < m \leq p_n} E(\Delta_m \Delta_j).$$

Proceeding in a similar fashion as in deriving the variance of J_1 , the lemma follows.

Lemma 4: (Volkonskii and Rozanov, 1959) *Let V_1, \dots, V_L be strongly mixing random variables with respect to the σ -algebras $\mathcal{F}_{i_1}^{j_1}, \dots, \mathcal{F}_{i_L}^{j_L}$ respectively with $1 \leq i_1 < j_1 < i_2 < \dots < j_L \leq n$, $i_{l+1} - j_l \geq w \geq 1$ and $|V_j| \leq 1$ for $j = 1, \dots, L$. Then*

$$\left| E\left(\prod_{j=1}^L V_j\right) - \prod_{j=1}^L E(V_j) \right| \leq 16(L-1)\alpha(w)$$

where $\alpha(w)$ is the strongly mixing coefficient.

5 Concluding remarks

In conclusion we like to note that Hyndman and Yao (2002) also introduced two alternative kernel smoothers of the conditional density, both aimed at removing negativity. Unlike the RNW smoother which is explicitly defined in terms of the data observations, these estimators are obtained implicitly through a minimization procedure. The implicit formulation has two disadvantages. First, convergence of the algorithms is far from guaranteed, especially when the dimension of the covariate is more than 1. Secondly, asymptotic study of the estimators is complicated. In contrast, the RNW smoother allows direct asymptotic analysis. Moreover, it is straightforward to implement in practice whatever the dimension of the covariate.
